Crestal Bone Loss around Dental Implants: Platform Switching vs Platform Matching—A Retrospective Study

Rashmita Nayak, Raghu Devanna, Anand M Dharamsi, Jeevan Shetty, Rizwan Mokashi, Sourav Malhotra

ABSTRACT

Aim: The objective of this study was to determine the vertical and horizontal marginal bone levels in platform-switched and platform-matched dental implants.

Materials and methods: In the present study, 50 dental implants were placed in 50 patients over a 1-year period. Measurement was performed from the implant shoulder to the most apical and horizontal marginal defect by periapical radiographs to examine the changes of peri-implant alveolar bone before and 12 months after prosthodontic restoration delivery.

Results: These marginal bone measurements showed a bone gain of 0.53 ± 0.98 mm in the vertical gap and 0.52 ± 0.93 mm in the horizontal gap of the platform matching, while in the platform switching, a bone gain of 1.33 ± 1 mm in the vertical gap (p < 0.05) and 1.60 ± 0.56 mm in the horizontal gap was found. Statistically significant difference was found for bone regeneration in the vertical gap between the two groups (p < 0.05) using t-test with Statistical Package for the Social Sciences (SPSS) statistical test version 17.

Conclusion: The crestal bone around the implants can be preserved with platform-switching concept and it can be applied in clinical condition.

Clinical significance: The crestal bone around the implants can be preserved with platform-switching concept.

Keywords: Crestal bone, Dental implants, Platform switching.

INTRODUCTION

The presence of sufficient amount of bone and its quality, especially crestal bone around implant, can predict the successful outcome of dental implant. However, bone loss at the peri-implant site is quite common. Adell et al evaluated the marginal bone loss at the initial period of prosthetic loading. Implant failure is secondary to peri-implantitis and bone loss due to the initial crestal bone loss and bacterial invasion. This, in turn, results into occlusal overload. The loss of interproximal papilla could be due to loss of marginal bone and gingival contour.

Abrahamsson et al observed a 1.5 to 2.0 mm of crestal bone loss after 1 year of loading and after installation of a two-piece healing implant in a submerged modality. However, 2 mm of crestal bone remodeling resorption was observed in an experimental study in dogs. Hence, research is going on to reduce the crestal bone loss.

A bone loss of approximately 2 mm around the implant during the first year of implant placement is acceptable and considered as successful in Toronto Conference. The presence of sufficient amount of bone and its quality, especially crestal bone around implant, can predict the successful outcome of dental implant. However, bone loss at the peri-implant site is quite common. Adell et al evaluated the marginal bone loss at the initial period of prosthetic loading. Implant failure is secondary to peri-implantitis and bone loss due to the initial crestal bone loss and bacterial invasion. This, in turn, results into occlusal overload. The loss of interproximal papilla could be due to loss of marginal bone and gingival contour.

Conclusion: The crestal bone around the implants can be preserved with platform-switching concept and it can be applied in clinical condition.

Clinical significance: The crestal bone around the implants can be preserved with platform-switching concept.

Crestal Bone Loss around Dental Implants

The permanent metal ceramic crown was delivered operatively to the healing abutment surgery connection. Healing abutments were placed in all the individuals. Therefore, a second-stage surgery was carried out and the prosthetic restoration was delivered. Digital periapical radiographs of the dental implants were recorded at different time points: before loading (baseline); immediately after loading; and 1, 3, 6, and 12 months after loading. The implant shoulder was considered as the reference point for measuring vertical and horizontal dimensions (vertical bone gap and horizontal bone gap) of the mesial and distal peri-implant marginal bone defect; the same measurements were used to evaluate bone remodeling through the 12 months of follow-up.

The data are presented as means ± standard error and were analyzed by SPSS version 17 at a significance level of p ≤ 0.05. Independent and paired sample t-tests were conducted and comparisons were computed by means with repeated measures within and between groups respectively. The statistical evaluation of the difference in mesial and distal marginal bone gap loss was accomplished with independent t-test.

**Inclusion Criteria**

- Nonsmoking or smoking history of <6 cigarettes per day.
- Good oral hygiene with full-mouth plaque score ≤ 25% at baseline; full-mouth bleeding on probing ≤ 25% at baseline; probing depth of pocket adjacent to the implant site in six aspects of the teeth ≤ 3 mm.
- Periodontal attachment level adjacent to the implant site at six aspects of the teeth ≤ 2 mm.
- No periapical lesions.

**Exclusion Criteria**

The exclusion criteria were as follows: patients with any local or systemic disease, smoking more than 6 cigarettes/day, betel nut or tobacco chewing, alcoholism, pregnancy or breastfeeding, long-term oral medications, oral parafunction, nontreated periodontal disease, and inadequate bone volume.

**RESULTS**

There was no statistically significant difference for demographic data between the groups. In total, 50 patients (25 men and 25 women) received 50 dental implants in the present study. Overall, 25 platform-matched implants were implanted in a total of 25 patients (mean age: 43.8 ± 20.7 and 44.1 ± 24 years). On the contrary, 25 platform-switched implants were placed in 25 patients (mean age: 43.1 ± 28 and 42.3 ± 16.7 years).

Table 1 indicates vertical bone gap variations from platform-switched implants. The mean vertical bone gap in platform-switched implants was 3.06 ± 1.11 mm before loading; 3.12 ± 1.01 mm mean immediately after loading;...
3.04 ± 1.21 mm mean 1 month after loading; 2.86 ± 1.30 mm mean 6 months after loading; and 2.16 ± 0.94 mm mean 12 months after loading. Statistical analysis showed a statistically significant difference (p < 0.05) between the baseline and 6 months, and between the baseline and 12 months in all the vertical measurements (Table 1).

Horizontal bone gap variations in platform-switched implants are shown in Table 1. The mean horizontal bone gap in platform-switched implants was 2.46 ± 1.22 mm mean before loading; 2.81 ± 1.30 mm mean immediately after loading; 2.26 ± 1.23 mm mean 1 month after loading; 2.22 ± 0.90 mm mean 6 months after loading; and 2.27 ± 0.91 mm mean 12 months after loading. Statistical analysis showed a statistically significant difference (p < 0.05) between the baseline and 6 months, and between the baseline and 12 months in all the horizontal measurements (Table 1).

Horizontal bone gap variations in platform-matched implants during the 12-month study period. The mean vertical bone gap in platform-matched implants was 2.26 ± 1.1 mm before loading; 2.17 ± 0.84 mm mean immediately after loading; 2.12 ± 0.90 mm mean 1 month after loading; 4.18 ± 0.85 mm mean 3 months after loading; 2.06 ± 1.12 mm mean 6 months after loading; and 1.55 ± 0.82 mm mean 12 months after loading. There was a statistically significant finding (p<0.05) between the baseline and 12 months in all the horizontal measurements (Table 1).

Test used: t-test significance: p<0.05; SD: Standard deviation

3.04 ± 1.21 mm mean 1 month after loading; 2.86 ± 1.30 mm mean 6 months after loading; and 2.16 ± 0.94 mm mean 12 months after loading. Statistical analysis showed a statistically significant difference (p<0.05) between the baseline and 6 months, and between the baseline and 12 months in all the vertical measurements (Table 1).

Horizontal bone gap variations in platform-switched implants are shown in Table 1. The mean horizontal bone gap in platform-switched implants was 2.46 ± 1.22 mm mean before loading; 2.56 ± 1.31 mm mean immediately after loading; 2.46 ± 1.12 mm mean 1 month after loading; 2.26 ± 1.23 mm mean 3 months after loading; 2.22 ± 0.90 mm mean 6 months after loading; and 2.27 ± 0.91 mm mean 12 months after loading. Statistical analysis showed a statistically significant difference (p<0.05) between the baseline and 6 months, and between the baseline and 12 months in all the horizontal measurements (Table 1).

Table 2 indicates the vertical marginal bone gap variations in platform-matched implants during the 12-month study period. The mean vertical bone gap in platform-matched implants was 2.26 ± 1.1 mm before loading; 2.17 ± 0.84 mm mean immediately after loading; 2.12 ± 0.90 mm mean 1 month after loading; 4.18 ± 0.85 mm mean 3 months after loading; 2.06 ± 1.12 mm mean 6 months after loading; and 1.55 ± 0.82 mm mean 12 months after loading. There was a statistically significant finding (p<0.05) between the baseline and 12 months in all the horizontal measurements (Table 2).

The horizontal bone gap results in platform-switched implants are shown in Table 2. The mean horizontal bone gap in platform-switched implants was 2.33 ± 0.97 mm mean before loading; 2.37 ± 1.1 mm mean 3 months after loading; 2.23 ± 0.99 mm mean 6 months after loading; and 2.16 ± 0.77 mm mean 12 months after loading. Statistical analysis showed no statistically significant differences between the baseline and the rest of the time points in any of the horizontal measurements (Table 2).

These marginal bone measurements showed a bone gain of 0.53 ± 0.98 mm in the vertical gap and 0.52 ± 0.93 mm in the horizontal gap of the platform matching, while in the platform switching, a bone gain of 1.33 ± 1 mm in the vertical gap (p<0.05) and 1.60 ± 0.56 mm in the horizontal gap was found. Only a statistically significant difference was found comparing bone gains in the vertical gap between the two groups (p<0.05).

**DISCUSSION**

During the 1-year study period in the present study, there was lesser marginal bone loss observed in platform-switching concept compared with abatement diameter of the matching bone implant.

From the available literature, it has been confirmed that crestal bone resorption can be reduced with a major contributing factor, such as platform-switching method. Biological width is important in maintaining the soft and hard tissues. The IAJ is shifted inwardly in the platform-switching technique. This makes the inward shift of the inflammatory infiltrate away from the crestal bone and creates a horizontal biologic width and hence preserves the crestal bone. At the same time, it decreases the chance of bone resorption by shifting of the micro-gap away from the crestal bone.7

The etiology of bone remodeling was believed to be dependent on the localized inflammation of the peri-implant soft tissue.8 This is supported, especially at the
Crestal Bone Loss around Dental Implants

IAJ for micro-gap, and the abutment site was infiltrated by inflammatory cells, where it is always possible to detect bacterial infiltration, as reported by Jansen et al. In the present study, both platform-switched and platform-matched implant groups exhibited reduced vertical and horizontal gaps at the end of 12 months. There was a greater reduction in the mean marginal bone gaps in the platform-switched dental implants, with only statistically significant differences between the two groups at the end of 12 months in the vertical measurements, where the platform-switched implants presented more mean reduction in the vertical marginal bone gap (2.16 ± 1.02 mm) than the platform-matched implants did (1.55 ± 0.82 mm). Similar results have been reported in previous studies, with a better marginal bone level in platform-switched implants. In addition, the platform-switching concept helps to obtain satisfactory long-term esthetic results by the mean marginal bone reduction obtained in vertical and horizontal gaps.

A recent systematic review and meta-analysis study with a total of 26 studies involving 1,511 platform-switched implants and 1,123 platform-matched implants indicated that platform switching within 18 months following crown placement had a lower vertical marginal bone loss (0.23 mm) compared with platform-matched implants. After more than 1 year of function, slight soft tissue loss was observed in platform-switched implants; hence, the results of soft tissue should be interpreted with caution for a better long-term successful treatment. The authors concluded that platform switching may have an indirect protective effect on implant hard tissue outcomes.

The platform-switching concept is a recent approach that aims to reduce or control the bone loss at the horizontal component; it refers to the use of a smaller diameter abutment on a larger diameter implant platform. Such a connection shifts the perimeter of the IAJ inwardly toward the central axis of the implant to preserve the marginal bone from stress concentration. It is also believed that crestal bone resorption can be reduced by inflammatory cell infiltration to long axis of implant and away from the crestal bone site and with an inward movement of IAJ. Moreover, crestal bone loss and soft tissue stability are influenced by the abutment collar length which controls the final crown margin location and the subsequent esthetic outcome.

All studies comparing the implants for platform-switching and nonswitching type suggested that implant for platform-switched type showed a lower resorption rate for marginal bone. Hürzeler et al. compared the loss of crestal bone around implants for platform-switched and nonplatform-switched type. There was 0.22 mm of mean crestal bone loss in platform-switched implants and nonplatform-switched implants, which was 2.02 mm. They also found that a 0.45 mm abutment reduction on either side is sufficient to avoid peri-implant bone loss. Another study by Cappiello et al found that the vertical bone loss for the platform-switched cases varied between 0.6 and 1.2 mm (mean: 0.95 ± 0.32 mm), while for the cases without platform switching, there was an average of 1.3 and 2.1 mm (mean: 1.67 ± 0.37 mm) of bone loss. In nonplatform-switched implants, 1 to 2 mm average of bone loss occurred, whereas there was minimal bone loss found in platform-switched implants.

Implant–abutment interface is a very important criterion for implant success. Platform switching increases the distance between IAJ and the crestal bone, thereby increasing the micro-gap to crestal bone distance, hence preserving the crestal bone, but it does not affect the width of the micro-gap. The precision fit of implant–abutment connection in Morse taper or internal hex implants offer an additional advantage of reduced micro-gap. So, the introduction of combination of Morse taper connection and platform switching can be a boon to implant dentistry.

CONCLUSION

The concept of crestal bone loss around the implant plays an important role for the overall success rate. Platform switching helps to prevent the bone loss around the implants and thus this concept must be used in clinical practice.
