How to improve Thin Endometrium in Cases of Female Infertility

1Gangadhar Sahoo, 2Vishy Agrawal, 3Ruchika Garg, 4Neharika Malhotra

ABSTRACT

Thin endometrium is frequently encountered during the treatment of female infertility. It is associated with lower implantation and pregnancy rates. Adequate growth is an integral step in endometrial receptivity and embryo implantation. Several modalities have been studied and include extended estrogen, pentoxifylline, tocopherol, low-dose aspirin, acupuncture, neuromuscular stimulation, L-arginine, vaginal sildenafil, granulocyte colony-stimulating factor (G-CSF), and stem cell therapy. Studies show that vaginal sildenafil appears to be the first-line therapy option, G-CSF appears to be a potential second option, while stem cell therapy appears a new promising treatment modality.

Keywords: Endometrium thickness, Granulocyte colony-stimulating factor, Infertility, Stem cell therapy, Thin endometrium.

INTRODUCTION

Uterine causes of infertility contribute to about 5 to 10% of cases. A fairly normal uterine cavity and endometrial lining are necessary in order to conceive and maintain normal pregnancy. Gonen and Casper1 and Elnashar et al2 reported that thin endometrium less than 7 mm is considered as an important sign determining the implantation potential and it has a significant correlation with the duration of follicular stimulation and also with age.

Thin endometrium results due to

• Permanent damage to basal endometrium
• Resistance of endometrium surface receptors to estrogen
• Decreased blood flow to the endometrium
• Overexposure to testosterone

The endometrium is the special epithelial lining of the uterus above the level of internal os. It has two layers: a superficial functional and a deep basal layer. Miva et al3 found that the growth of the endometrium depends on the blood flow to the endometrial cavity and the angiogenesis and the thin endometrium is characterized by high-flow impedance of uterine radial artery, poor epithelial growth, and decreased expression of vascular endothelial growth factor resulting in thin endometrium.

AGENTS USED TO INCREASE THE THICKNESS OF ENDOMETRIUM

Older Agents

Hormonal Adjustment

Endometrial proliferation is dependent on serum estrogen levels, which results in progressive growth of the functional endometrium in the proliferative phase. Based on this, patients with thin endometrium were offered supplemental exogenous estrogen. Chen et al4 studied the role of estrogens in the development of endometrium. They had randomized patients with the endometrial thickness <8 mm into two groups, and they found that the group which had received exogenous estrogen had a better development of endometrium than the group that did not.

Pentoxifylline and Tocopherol

Pentoxifylline (PTX) and tocopherol (vitamin E) combination had been found to improve endometrial thickness in patients with thin endometrium.5 Lédée-Bataille et al6 studied the role of PTX and tocopherol in combination for the development of endometrium and it was found that the patients who had received a dose of 400 mg had a better development of endometrial lining (thickness was increased by 1.3 ± 1 mm).
Acharya et al also studied the role of the combination and found that there were significant increases in the thickness of the endometrium at the end of treatment and also resulted in 40% pregnancy rate. The mechanism of action of PTX resulting in better development of endometrium is that it causes vasodilation and also decreases inflammation.

**Low-dose Aspirin**

Studies have shown that patients receiving low-dose aspirin showed a better development of endometrium. There is significant increase in the endometrium thickness in the group receiving it than in the group which does not. The mechanism explaining the role of low-dose aspirin is that it decreases the pulsatility index of the uterine artery and thus increases the blood flow to the endometrium, resulting in a better growth.

**Acupuncture**

Acupuncture, one of the oldest interventions of traditional Chinese medicine, has been found to improve many gynecologic conditions including infertility. Stener-Victorin et al found that electroacupuncture decreases the uterine artery blood flow resistance and thus increases the blood flow. Ho et al in a randomized trial had also found that acupuncture results in a significant reduction in uterine artery impedance, resulting in increased blood flow and a better growth without a significant difference in pregnancy rates.

**L-Arginine**

L-arginine is a nitric oxide donor and relaxes vascular smooth muscles of endometrium as tried by Takasaki et al and it has been shown to decrease the resistive index.

**Nitroglycerine Patch**

It improves the uterine blood flow, but it is associated with side effects like headache and hypertension.

**Recent Agents**

**Vaginal Sildenafil**

It is a potent and selective inhibitor of cyclic guanosine monophosphate (cGMP)-specific phosphodiesterases that inhibit the breakdown of cGMP and potentiate the effect of nitric oxide on the vascular smooth muscle.

Sher and Fisch reported that the pulsatility index decreases after treatment with sildenafil, indicating increased diastolic blood flow after sildenafil administration. Zinger et al found that there is a significant increase in the endometrium thickness in two infertile patients with the thin endometrium receiving it. Takasaki et al found that vaginal sildenafil significantly increased the endometrium thickness from 7.1 to 9.4 mm (p < 0.01), with a 50% pregnancy rate after 12 *in vitro* fertilization (IVF) cycles.

**Granulocyte Colony-stimulating Factor**

Granulocyte colony-stimulating factor is described as a hematopoietic growth factor that has currently been shown to have important functions in nonhematopoietic cells, such as the endometrium. Lacena and Moreno-Ortiz reported that a patient with thin endometrium (<5.7 mm) during an *in vitro* maturation cycle who was given 300 µg of G-CSF on the day of oocyte retrieval showed a significant growth in endometrium. Recently, Barad et al tried to increase the use of G-CSF for increasing the endometrial thickness in all patients undergoing IVF or frozen embryo transfer, regardless of endometrial thickness.

**Stem Cell Therapy**

Studies have supported the presence of progenitor cells in the endometrium and these cells proved to have a high regenerative capacity. Cervello et al demonstrated that endometrial stem cells are able to generate human endometrium after transplantation in mice renal capsules. Taylor also demonstrated the role of endometrial progenitor cells in the development of endometrium.

**Endometrial Scratch**

A few randomized controlled trials have shown that endometrial scratching in the luteal phase of one cycle prior to IVF cycle increases the endometrial thickness and pregnancy rate. The rationale of using endometrial cratch is based on the fact that the tissue injury procedures such as endometrial biopsy induces stem cell differentiation and increases endometrial receptivity.

**Platelet-rich Plasma**

It has been shown to be useful in cases of thin endometrium as well as in cases of implantation failure.

**CONCLUSION**

Receptive endometrium with proper endometrial development plays an important role in embryo implantation. Among multiple available treatment options, vaginal sildenafil during the stimulation cycle appears to be a reasonable first-line treatment option. Stem cell therapy
appears to have a great role in the refractory cases; however, more research regarding safety, effectiveness, and cost is required.
