CASE REPORT

ABSTRACT

Waldeyer’s ring is the primary site of non-Hodgkin’s lymphoma (NHL) involvement in approximately 5 to 10% of all lymphoma patients. Lymphomas arising from base of the tongue are less frequent, accounting for 7% of all primary Waldeyer’s ring NHLs. We report a case of NHL involving the base of tongue in a 30-year-old man who complained of dysphagia and swelling of neck. Clinical examination, radiographic, histopathological features, current understanding of disease with review of literature is offered.

Keywords: Waldeyer’s ring, Lymphoma, Dysphagia.

INTRODUCTION

Non-Hodgkin’s lymphoma (NHL) consists of a group of malignancies of the cells of the lymphocyte developmental pathway of the immune system. The different histological subtypes vary widely in their clinical behavior, progress and management, and there is some evidence that the different subgroups of NHL have differing epidemiological features.1 The exact cause of these cancers is not fully understood but it is believed to be caused by an altered or depressed immune system.

CASE REPORT

A 30-year-old male patient presented with complaints of dysphagia to solids and swelling involving left side of neck for past 3 months. Patient did not give history of fever or night sweats.

On examination of the neck, a 4 × 3 cm firm nontender, single node with restricted mobility was seen in left level II region and another node of size 2 × 2 cm palpated in the right level II area. On intraoral examination, a red, smooth lobulated swelling with some areas of ulceration was seen occupying the posterior third of tongue in the midline extending below (Fig. 1). Video laryngoscopy revealed a lobulated swelling involving posterior 1/3rd of tongue extending onto left vallecula and just extending to epiglottis (Fig. 2). Rest of larynx and hypopharynx were normal.

Patient was subjected to complete hemogram which was normal except for lymphocytosis and raised ESR. Peripheral smear showed no evidence of blasts cells. Renal function and liver function tests were normal and patient was negative for HIV.

CT PNS and neck with contrast revealed, soft tissue density in posterior aspect of tongue of size 4 × 2.8 cm involving anterior surface of epiglottis and vallecula and bilateral cervical adenopathy with the largest node measuring 4.2 × 2.5 cm (Fig. 3). CT chest showed no evidence of mediastinal adenopathy, parenchymal or pleural disease. CT abdomen with contrast showed liver and spleen to appear normal in size and did not reveal any parenchymal lesion and intra-abdominal nodes.

DIAGNOSIS

Biopsy showed a submucosal lesion made up of atypical small blue cells showing increased number of mitosis suggestive of

Fig. 1: Intraoral examination showing lesion in posterior 1/3rd of tongue
categories: Hodgkin’s lymphoma and non-Hodgkin’s lymphoma (NHL). Non-Hodgkin’s lymphoma is a heterogeneous group of malignancies characterized by an abnormal clonal proliferation of T cells, B cells, or both. The majority of the adult non-Hodgkin’s lymphomas are of B cell origin.\(^2\) The exact cause of non-Hodgkin’s lymphoma remains unknown. However, research has focused on some factors that may contribute to the development of lymphoma, including genetic factors, impaired immune system and viruses, such as HIV.

NHL may arise in lymph nodes with or without involvement of lymphoid organs, such as spleen, and extralymphatic lymphoid tissues, such as Peyer’s patches and Waldeyer’s ring. They also have a great tendency to affect extralymphatic organs. The head and neck is the second most common region for extranodal lymphoma, with the first being the gastrointestinal tract. Extranodal NHLs of the head and neck region occur predominantly in patients between 50 and 60 years of age.\(^3\) The male-to-female ratio is 1.6:1.\(^4\) Among various head and neck sites, Waldeyer’s ring is the most often site involved.\(^5\)

Waldeyer’s ring consists of lymphoid tissue of the nasopharynx and oropharynx and comprises the adenoids (pharyngeal tonsil), pharyngeal openings of the Eustachian tube (tubal or Gerlach’s tonsils), palatine tonsils, as well as the lymphoid tissue of the soft palate and posterior third of the base of tongue (lingual tonsil).\(^5\)\(^7\) Together, these form a circular structure guarding the entrance to the upper aerodigestive tract.\(^5\)

Waldeyer’s ring is the primary site of NHL involvement in approximately 5 to 10% of all lymphoma patients. Of all Waldeyer’s ring NHLs, the tonsil is the most frequent site, followed by the nasopharynx. Lymphomas arising from the base of the tongue are less frequent, accounting for 7% of all primary Waldeyer’s ring NHLs.\(^5\)\(^9\)\(^10\) The possible differential diagnosis includes squamous cell carcinoma (SCC), which is the most common malignancy of the tongue base,\(^11\) salivary gland malignancy, (adenoid cystic carcinoma or mucoepidermoid carcinoma)\(^12\) and infection processes, such as tuberculosis were also considered.\(^13\)

**DISCUSSION**

Malignant lymphoma is the generic term given to tumors of the lymphoid system. These tumors are divided into two major
diffuse large B-cell lymphoma (DLBCL) (Fig. 4). Patient subsequently underwent bone marrow biopsy which showed infiltration with lymphoma cells. Immunohistochemistry was positive for CD 45 and CD 20 and negative for CD 3 suggestive of B cell NHL. The final diagnosis made was that of diffuse large B cell lymphoma of Waldeyer’s ring involving posterior third of tongue with bone marrow involvement (stage IV disease).

Patient received eight cycles of chemotherapy with CHOP regime (cyclophosphamide, doxorubicin, vincristine, prednisolone). Rituximab could not be added due to logistics. The intraoral mass disappeared at the end of the 4th cycle of chemotherapy and patient is currently disease-free of disease at 2 years of follow-up.

**Fig. 4:** HPE showing submucosal lesion made up of atypical small blue cells with increased number of mitosis suggestive of diffuse large B-cell lymphoma

**Fig. 4:** HPE showing submucosal lesion made up of atypical small blue cells with increased number of mitosis suggestive of diffuse large B-cell lymphoma
The DLBCL is the most common histological type of primary oral and oropharyngeal NHL forming 66 to 75% of all lymphomas. Diffuse large B-cell lymphoma is composed of patternless sheets of large, transformed lymphoid cells with variable cytoplasmic content and enlarged, vesicular nuclei containing dispersed (activated) chromatin that allows one to several nucleoli to become visible in each nucleus. This turns out to be the largest group of lymphomas involving the Waldeyer’s ring.8

Generally, CHOP-based chemotherapy with rituximab is the current standard of treatment.14 Involved field RT is added in bulky early stage disease as consolidation. According to the international prognostic index (IPI) established for patients aged less than 60 years, the outcome of patients with extranodal DLBCL is similar to that of patients with nodal DLBCL.14

CONCLUSION

The vast majority of lymphomas of the oropharyngeal region are of the B-cell rather than the T-cell type. Treatment recommendation for diffuse large B-cell lymphoma is generally identical for nodal and extranodal diseases. The use of chemotherapy is based on the principle that DLBCL of the head and neck must be considered a localized manifestation of systemic disease.14 The above-mentioned case report highlights a rare presentation of extranodal lymphoma presenting in an advanced stage with good disease control with chemotherapy.
