ABSTRACT

Endometrial 3D power Doppler indices change significantly during the normal menstrual cycle. Vascularity indices of the endometrial and subendometrial vessels increase throughout the proliferative phase of the menstrual cycle, reaching a maximum value 2 to 3 days prior to ovulation. From this peak, vascularity indices decrease and reach a nadir 2 to 5 days after ovulation. Reduced endometrial perfusion assessed by 3D power Doppler ultrasound is most likely related to increased uterine contractility. If prolonged, it may cause endometrial hypoxia, leading to detrimental effect on implantation potential. In normal spontaneous menstrual cycles, endometrial and subendometrial perfusion is negatively affected by serum estradiol concentrations, which can explain why patients with hyperstimulation have lower endometrial and subendometrial blood flow during the early luteal phase. Our results indicate that 3D power Doppler implantation markers are crucial for planning a single embryo transfer in order to select the most suitable cycle for transfer of a single cryopreserved embryo.

INTRODUCTION

Implantation is the penetration of the embryo in the uterine endometrium. This process is characterized by taking place only during a very specific period called ‘implantation window’. Between days 19 to 22 of the menstrual cycle, synchronization between the embryo development blastocyst stage and endometrium receptivity occurs.

Current assisted reproduction techniques (ART), especially in vitro fertilization (IVF), makes possible to know the implantation process and the best conditions to achieve a successful outcome. Today we know that obtaining a pregnancy after embryo transfer is closely related to the embryo quality, endometrium receptivity and the transfer technique.

Currently, it is firmly believed that to increase pregnancy rates and decrease multiple gestations through ART, a better knowledge of implantation markers is required. Ultrasonography, color Doppler, the recently introduced 3D ultrasonography and power Doppler angiography offer the possibility to assess the uterine and ovarian markers of implantation to be able to use them in our clinical practice. As it is described below, endometrial ultrasound and Doppler parameters give us the information related to endometrial receptivity and can be used as implantation markers.

ULTRASOUND IMPLANTATION MARKERS

Real-time ultrasonography allows us the study of two main implantation markers: Endometrial thickness and endometrial morphological patterns. Pulsed and color Doppler assessment is applied to the study of different variables of uterine and endometrial perfusion that are also used as receptivity factors. Three-dimensional ultrasound and power Doppler angiography (3D US-PDA) have the advantage of simultaneous assessment of endometrial volume and endometrial blood flow.
However, in the conception cycles there is an accelerated increase in the endometrial thickness during the luteal phase that reaches significant differences regarding to that in nonconception cycles 14 days after the day of oocyte retrieval.\textsuperscript{8,11}

As an implantation marker, endometrial thickness is characterized by its significant sensitivity (95-100%), but also shows a high number of false positives (78-97%);\textsuperscript{10} therefore, the main advantage is a high negative predictive value (87-100%) (Table 1). An endometrial thickness lower than 7 mm on the day of hCG administration is considered an acceptable marker for nonreceptive endometrium. It has also been reported that implantation and pregnancy rates are negatively affected by the endometrium being thicker than 14 mm,\textsuperscript{12} although data from recent studies do not support this finding.\textsuperscript{13,14} On the other hand, a very thin (<6 mm) or very thick (>13 mm) endometrium has also been associated with an increase in early miscarriages.\textsuperscript{15}

In a donor oocyte program with hormone replacement therapy (HRT) it is proven that pregnancy rates and endometrial thickness decrease at the same time.\textsuperscript{16} When endometrial thickness is equal or greater than 9 mm a pregnancy rate of 68% is achieved, diminishing to 20% when endometrial thickness is less than 6 mm.\textsuperscript{16} Although it is possible to achieve pregnancies with a thin endometrium,\textsuperscript{17} this is always a bad predictive factor that requires further study of the endometrium.\textsuperscript{16} In a retrospective study of 1,228 IVF/ICSI (Intracytoplasmic sperm injection) cycles, endometrial thickness on the day of embryo transfer was positively associated with pregnancy rates. Improved pregnancy rates were found when the endometrium reached at least 10 mm and rates further improved with additional increases in endometrial thickness between 10 and 14 mm. Nevertheless, these authors did not find any significant difference in endometrial thickness between ongoing pregnancies and the ones resulting in a first-trimester loss.\textsuperscript{18} After a retrospective analysis of 897 IVF-ET cycles, an increased endometrial thickness on the hCG day administration is associated with an improved outcome, but this relationship also depends on patient age, length of ovarian stimulation and embryo quality. A thin endometrium is associated with reduced pregnancy rates only for the transfers of less good quality embryos.\textsuperscript{14} More recently, it was evaluated that the relationship between endometrial thickness and embryo implantation by a retrospective study on 1,294 IVF cycles with transfer of two blastocyst-stage embryos.\textsuperscript{19} The authors demonstrated a significant relationship between both variables. Pregnancy

rates increased gradually with increasing endometrial thickness. This relationship is independent of the patient age, the number and quality of embryos transferred. Nevertheless, good pregnancy rates can be achieved with endometrial lines of only 6 to 7 mm, when good-quality blastocysts are transferred.19

Three-dimensional technology has added to our daily practice in reproduction the use of endometrial volume as an implantation marker (Fig. 1B). Three. Our team has recently demonstrated an excellent intra- and inter-observer reproducibility of this measurement.20,21 The best intraclass correlation indices to obtain the endometrial volume and endometrial vascularity indices with the virtual organ computer-aided analysis (VOCAL) program are achieved working in the coronal or “C” plane with a rotational angle of 9° (Table 2).21

During spontaneous menstrual cycles, the changes in uterine/endometrial volume ratio proved a good correlation with the day of menstrual cycle.22 Endometrial volume increased significantly during the follicular phase, reaching a plateau around the time of ovulation and remaining relatively stable throughout the luteal phase.23,24 Parous women showed endometrial volumes significantly larger than nulliparous women.25 According to our results, basal endometrial volumes after ovarian simulation with single or multiple preovulatory follicles and midluteal endometrial volumes (Fig. 2A).

A pioneering study25 demonstrated that endometrial volume at the time of ET is related to pregnancy achievement. An endometrial volume larger than 2 ml could be a prerequisite for good endometrial receptivity given that pregnancy and implantation rates were significantly lower with a smaller endometrial volume.25 More recently, an endometrial volume of 2.5 ml on the day of ET has been proposed as a reliable threshold value to predict pregnancy after ET in IVF/ICSI cycles.26 The analysis of the endometrium on the hCG day by 3D ultrasonography in 80 infertile women undergoing a first IVF-ICSI cycle, proved that endometrial volume is significantly greater in women that got pregnant, whereas endometrial thickness is unchanged (Table 3). Other studies have not demonstrated that endometrial volume is predictive for pregnancy.27-31 This could be explained by methodological differences in volume calculation. Whereas we perform VOCAL program in plane C with a 9° rotational steps, some authors use a nonrotational method27-29 or apply the VOCAL program but delineating and measuring an inferior number of planes.30,31 In addition, endometrial volumes evaluated in different cycle day, such as the day of hCG administration, the day of oocyte retrieval or the day of embryo transfer, might be difficult to compare. Comparing endometrial volume before hCG administration with that on the day of oocyte retrieval, it significantly decreased after hCG

injection in women who conceived but not in those who did not conceive. Our group has recently published a prospective clinical study in eighty women who underwent IVF cycle. Endometrial volume was significantly increased in the pregnant group (38 cycles) comparatively with nonpregnant group (39 cycles). On the contrary, endometrial thickness and triple-line pattern did not show significant differences between both groups. According to our results, endometrial volume measured with 3D ultrasound is a useful parameter in predicting outcome cycle in IVF and ET procedure.

Other parameters have been assessed, such as the length and the width of the endometrium or the endometrial area, although no advantage overendometrial thickness or volume in using these parameters has been demonstrated.

### Endometrial Pattern

The endometrial pattern is the relative echogenicity that the endometrium presents with respect to the adjacent myometrium. Its importance as an implantation marker lies in that it reflects the degree of histological development.

During the proliferative phase of the menstrual cycle, the endometrium achieves a 'triple line' morphology (Fig. 3A) where the echogenic central line represents the uterine cavity and the outer echogenic lines reflect the basal layer of the endometrium or the interface between the endometrium and, the myometrium. The hypoechoic zones between the outer and central line are the functional layers of the endometrium. This image is attributed to the glandular disposition, reduced secretion and scarce stromal edema.

Data are presented as mean ± standard deviation or n (%) or a median (range).
During the secretory phase of the menstrual cycle, the endometrium acquires a hyperechogenic morphology (Fig. 3B) that is due to stromal edema, spiralization and secretion of the endometrial glands caused by the action of progesterone. However, since a correlation between echogenicity and progesterone has not been demonstrated, other factors, such as androgen and gonadotropin effects, could explain these changes.

The subendometrial halo or uterine junctional zone between the endometrium and the myometrium is a distinct compartment of the myometrium comprising tightly packed muscle cells and an increased vascularity.

Although initially four different myometrial echogenicity patterns were described it were lately reduced to three, because a ‘triple line’ pattern as the only positive implantation marker results more predictive (Fig. 3C). The endometrial pattern does not appear to be influenced by the ovarian stimulation protocol and it is also present when hormonal replacement for frozen ET is carried out.

Significant differences of the endometrial morphological pattern between hCG day and the transfer day have not been observed either.9

A ‘triple line’ endometrium is the ultrasound marker that most accurately reflects endometrial receptivity, while the ‘nontriple-line’ pattern is frequently associated with nonconception cycles, although the possibility of implantation must never be excluded. Just as with thickness, the ‘triple line’ endometrial pattern has high sensitivity (79-100%) but an elevated percentage of false positives (57-91%) also, subsequently it has an additional interest by its high negative predictive value (75-100%) (Table 1). Although achieving a pregnancy with a ‘nontriple-line’ pattern is possible, its frequency is low.

Since, the increase in echogenicity during the follicular phase is the best endometrial parameter to indicate low receptivity, an attempt has been made to evaluate this characteristic by computerized analysis of endometrial morphology. During the menstrual cycle, myometrial echogenicity increases significantly in both spontaneous and stimulated cycles, but the most important fact is that implantation and pregnancy rates decrease progressively as myometrial echogenicity increases on the day of hCG administration. Therefore, there is an inverse relationship between the extent of endometrial echogenicity transformation and the possibility of pregnancy. More recently it has been also demonstrated a positive relationship between trilaminar pattern with successful implantation and ongoing pregnancy in IVF/ICSI cycles using antagonists. Nevertheless, some authors think that combined analysis of endometrial thickness and pattern on the day of hCG administration is a better predictor of the outcome of IVF/ICSI-ET and may be more helpful for patient counseling than the separate analyses.

The normal luteal endometrial pattern has been also implied as an implantation marker. A nonhomogeneous hyperechogenic pattern three days after ET has been associated with lower pregnancy rates. In addition, the midluteal endometrial pattern of women with unexplained infertility is related to the chance of pregnancy. The pregnancy rate is significantly higher when the endometrium

Figs 3A to C: Endometrial echogenicity patterns: (A) Multilayered proliferative endometrium or ‘triple line’ pattern; (B) Nonmultilayered endometrium; (C) Secretory endometrium
displays a homogenous hyperechogenic pattern comparatively with nonhomogeneous pattern. Endometrial pattern and thickness were not predictive of pregnancy outcomes in oocyte donation cycles, both prior and following progesterone administration. However, in frozen embryo transfers, it was showed that an increase in progesterone dosage when there is not a mid luteal nonhomogeneous pattern could lead an increased pregnancy rate.

**Uterine Doppler**

Doppler studies have demonstrated that the resistance of uterine and endometrial arteries decreases significantly during the mesoluteal phase, i.e. in the period of embryo implantation. It is probable that these vascular changes play a significant role in the implantation process because they are present from the beginning of the embryo nidation. In rodents, it has been proven an increase of the capillary permeability 24 hours before the blastocyst endometrium contact that takes place at the invasion site due to the local mediation of prostaglandins. Between the 6 and 12 postovulatory days the endometrium capillaries experience a progressive dilation acquiring a sinusoidal appearance, while the syncytiotrophoblast invades the endometrium. Around the 11 to 12 day, the uteroplacental circulation is fully established when maternal blood flows into syncytiotrophoblast lacunae.

Goswany, Williams and Steptoe demonstrated that the blood flow in the uterine arteries determines IVF success and that the uterine receptivity improved by increasing the vascular perfusion with HRT. Despite of the many studies that have been published since, there is no consensus on the importance of Doppler studies of these arteries in ART (Fig. 4). A substantial group of authors found significant differences in uterine arteries resistance between cycles with or without pregnancy, yet another important group does not observe this. These contradictory results are due to significant methodological variations, such as the ovarian stimulation protocol used, the cycle’s day when the Doppler study was carried out or the sonographic examination route.

Optimal uterine receptivity seems to occur when the mean pulsatility index of both arteries ranges between 2 and 3, the implantation and pregnancy rates significantly decreasing when pulsatility is over three or four or when diastolic flow is absent in the Doppler waveform. These limits have been proposed as a clinical marker to indicate the convenience to transfer or not the embryo. In doing so, its ability to predict uterine receptivity presents high sensitivity (96-100%) and a high negative predictive value (88-100%) although it has low specificity (13-35%) and positive predictive value (44-56%).

The relationship between uterine Doppler, endometrial and subendometrial blood flow assessed by 3D power Doppler angiography during stimulated and natural cycles has been evaluated. Several authors conclude that uterine Doppler is a poor reflection of subendometrial blood flow and its measurement cannot represent endometrial blood flow during stimulated cycles.

**2D and 3D Endometrial Doppler**

Endometrial Doppler should reflect more appropriately the endometrial perfusion and uterine receptivity because the endometrium is the place where implantation occurs. Uterine and endometrial blood flows perform in a similar way during the menstrual cycle. Nevertheless, they show a weak correlation when evaluated by velocimetric indices. During the luteal phase, the vascular endothelial growth factor (VEGF) expression is increased in the endometrium and there is a greater angiogenic activity. Recently, a close relationship between a strong VEGF expression in the endometrium and a successful outcome of implantation has been demonstrated.

Doppler study allows us to evaluate endometrial blood flow by means of analyzing flow velocity waveforms of subendometrial and endometrial arteries and the color mapping by 2D or 3D ultrasound. Vascular resistance in the endometrial spiral arteries or the subendometrial radial arteries (Fig. 5), also called
intramyometrial subendometrial arteries, is found to be decreased on the day of oocyte retrieval or ET in patients who achieve pregnancy, although every author cannot find it. In an intrauterine insemination program, we observed that the peak systolic velocity of the dominant uterine artery was significantly higher in the midluteal phase in the cycles in which pregnancy was achieved. Moreover, subendometrial radial arteries pulsatility was the only parameter that improved in those cycles where pregnancy was achieved after a previous nonconceptional cycle, except when implantation failed and subsequently a miscarriage or ectopic pregnancy was diagnosed.

Color mapping of endometrial vascularity can be classified in various types according to the degree of penetration into the endometrial thickness, using conventional color or power Doppler. In this way we differentiate four types of endometrial blood flow:

- Type 0 or negative flow, when only the surrounding myometrial vessels are seen nonreaching the endometrium
- Type I or peripheral flow, if the color signal reaches the hyperechogenic outer layer of the endometrium
- Type II or intermediate, when color mapping fills in the outer half of the endometrial hypoechogenic thickness; and
- Type III or central flow, if the vessels reach the endometrial cavity invading the entire endometrial thickness (Figs 6A and B).

It has been proposed that the endometrial and subendometrial area should be taken as a unity when the uterine perfusion is assessed by color Doppler, since there is no difference between the endometrial and subendometrial blood flow regarding to the possibility of achieving pregnancy. Nevertheless, color mapping is directly related to the sensitivity of the equipment and the adequate angle of insonation applied, so it is very important to always use the same characteristics, especially when recording the minimum velocity. For this reason, power Doppler is more reliable because signal amplitude mapping detects lower blood flow velocities and is unaffected by the angle of insonation. In general, endometrial color mapping has been evaluated in a subjective way although the color area can also be quantified.

The absence of color mapping of the endometrium and subendometrial areas means an absolute implantation failure or a significant decrease of the implantation rate. Conversely, the pregnancy rate increases when the vessels reach the subendometrial halo and endometrium. The presence of vessels within the endometrium is associated with a thicker endometrium, which suggests a correlation between the endometrial perfusion and endometrial growth. On the other hand, the absence of endometrial-subendometrial blood flow is accompanied by a high uterine artery resistance. Women with a higher...
endometrial flow area by power Doppler study have a greater probability of pregnancy, whereas below 5 mm² it is difficult that implantation will take place even with an adequate endometrial thickness.⁸⁹ We have not found significant differences in endometrial thickness, uterine and endometrial blood flow between conception and nonconception cycles after intrauterine insemination. On the contrary, all these parameters present higher values on the day of hCG administration in these cycles that achieve pregnancy by IVF. Nevertheless, only endometrial thickness and the uterine implantation index combining ultrasound and Doppler parameters show significant differences (Table 4). When pregnancy is achieved but endometrial–subendometrial flow on the day of ET cannot be seen, more than a half of these pregnancies will end in spontaneous miscarriage.⁸⁸ This suggests that the development of the endometrial vascular network should be important for the support of the first stages of pregnancy.

As mentioned above, three-dimensional ultrasound allows studying not only the endometrial volume but also the complete endometrial perfusion (Fig. 7A). A specific software named VOCAL performs an automatic quantification of endometrial vascularization by three 3D power Doppler indices.⁹³ The vascularization index (VI) estimates the number of color voxels inside the endometrial volume, thus expressing the number of endometrial blood vessels as a percentage. The flow index (FI) is the average color value from all the color voxels, depicting the mean intensity of the endometrial blood flow. The vascularization flow Index (VFI) is the average color value out of all the color and gray voxels, meaning the vascularization as well as the blood flow, in other words, the perfusion inside the endometrium (Fig. 7B).⁹³

Endometrial 3D power Doppler indices change significantly during the normal menstrual cycle. These vascularity indices increase during the proliferative phase reaching a maximum 2 to 3 days before ovulation. From this peak, vascularity indices decrease to reach a nadir 2 to 5 days after ovulation. Afterwards, endometrial vascular indices increase progressively along the rest of the luteal phase. Subendometrial blood flow experiences parallel changes but shows higher values of the vascularity indices.²⁴,⁹⁴ A reduced endometrial blood flow after ovulation could be related to an increased uterine contractility⁹⁵ and may lead to endometrial hypoxia during the implantation period.⁹⁶

Endometrial and subendometrial blood flows assessed in the same patients by 3D power Doppler indices are significantly lower in stimulated than in natural cycles.⁹⁷ It has also been reported that endometrial and subendometrial blood flows are negatively affected by serum estradiol concentrations, but they are not affected by other factors, such as women age, smoking habits, or types of infertility or parity, during IVF treatment.⁹⁸ This fact could explain that ovarian hyper-responders tend to have lower endometrial and subendometrial blood flows during the early luteal phase (+2 hCG day).⁹⁹ We have observed that endometrial FI is significantly decreased after pituitary suppression with a long GnRH protocol. Endometrial vascularity indices on the day of hCG administration do not show statistical differences between single and multifollicular ovarian development. Midluteal endometrial blood flow is found to be lower than preovulatory endometrial blood flow but differences do not reach statistical significance (Figs 2B to D). Small intramural fibroids do not seem to affect the endometrial and subendometrial blood flow;¹⁰⁰ on the other hand, patients with hydrosalpinx show a decreased endometrial and subendometrial blood flow.¹⁰¹

Even though most authors assess both endometrial and subendometrial vascularization as a pregnancy predictor,²⁸⁻⁻³¹,⁹⁰,⁹¹ we prefer to calculate only the 3D power Doppler indices of the endometrium.³² There are three reasons that account for this decision:

Figs 7A and B: (A) Three-dimensional power Doppler acquisition of endometrial vascularity on hCG administration day in an IVF cycle; (B) Power Doppler indices quantification by VOCAL software
1. The endometrium is the actual place where implantation occurs.

2. Subendometrial vascularization experiences the same changes as the endometrial one but with higher vascularity indices.

3. It is not possible to determine the subendometrial space accurately as it has been defined as an outer shell surrounding the endometrium with many different thicknesses—10 mm, 30 5 mm, 28, 29 or 1 mm. 31 The uterine wall thickness varies from patient to patient, so if we apply the same shell thickness, the vessels in the subendometrial zone will vary greatly from patient to patient, diminishing the reliability of the results. The only way to accurately define the subendometrial space would be applying a single percentage for the various thicknesses of the uterine wall. Furthermore, the endometrial vascularization is well defined as it is, within the limits of the myoendometrial junction.

Some authors have proved that subendometrial vascularity indices may behave as predicting factors for pregnancy on the transfer day 28 and the day of hCG administration. 29, 32 Others cannot prove 3D power Doppler indices to be good predictors for pregnancy after follicle-stimulating hormone (FSH) stimulation 30 or in the oocyte retrieval day. 31 Recently it has been proposed the day of hCG administration as the best day to evaluate the uterine receptivity. 84 In frozen-thawed ET cycles, endometrial and subendometrial vascularity measured by 3D power Doppler ultrasound is not a good predictor of pregnancy if measured at one time point only. 90, 92 On the contrary, endometrial and subendometrial power Doppler indices are significantly higher in pregnant patients with live following stimulated IVF and frozen thawed-ET transfer than those who suffered miscarriage. 91

Our results out of 80 infertile women undergoing a first IVF-ICSI cycle show significantly increased endometrial indices of vascularization flow on the hCG day in the pregnant group (Table 3). 32 In addition, the ability of 3D parameters for pregnancy prediction seems to depend on the quality of the embryos transferred. When two or three grade embryos were transferred, the area under the receiver operating characteristic (ROC) curve of the endometrial volume and the endometrial vascularity indices was inferior to 0.65, although with no statistical significance. On the other hand, when none or only one grade 1 embryo was transferred, the ROC curve showed a significant area for all the parameters, being slightly greater for FI. A FI greater than or equal to 26.1 predicted gestation with a sensitivity

* 95% confidence interval
of 85.7% and a 27.6% false-positive rate (Table 5). The ROC analysis also demonstrated that the endometrial volume and 3D power Doppler indices predict significantly which pregnancies will carry on normally; however, no relationship with the possibility of multiple gestations has been found.

According to our results it can be assumed that the 3D sonographic and power Doppler implantation markers are specially related to pregnancy when the quality of the transferred embryos is not good enough or only one top embryo can be transferred. Therefore, in order to achieve a pregnancy, a good endometrial receptivity, as assessed by ultrasound markers, seems essential when only one top quality embryo is available for transfer. The majority of ET policies propose a reduced number of embryos to be transferred \(^{102,103}\) and the amount of cycles where only one embryo is transferred is progressively increasing \(^{104,105}\). At this point, we believe that the new 3D markers of endometrial receptivity could be useful to select the more suitable cycle for the transfer of a single embryo.
