ABSTRACT

Objective: The aim of this study to investigate the effects of different polymerization protocols on the cuspal movement in class II composite restorations.

Materials and methods: Human premolar teeth were prepared with class II cavities and then restored with composite and three-step and two-step etch-and-rinse adhesive systems under different curing techniques (n = 10). It was used a light-emitting-diode curing unit and the mode of polymerization were: standard (exposure for 40 seconds at 700 mW/cm²), pulse-delay (initial exposure for 6 seconds at 350 mW/cm² followed by a resting period of 3 minutes and a final exposure of 37 seconds at 700 mW/cm²) and soft-start curing (exposure 10 seconds at 350 mW/cm² and 35 seconds at 700 mW/cm²). The cuspal distance (µm) was measured before and after the restorative procedure and the difference was recorded as cuspal movement. The data were submitted to two-way ANOVA and Bonferroni test (p < 0.05).

Results: The type of adhesive system did not influenced the cuspal movement for all the curing methods. Standard protocol showed the highest values of cuspal movement and was statistically different from the pulse-delay and soft-start curing modes.

Conclusion: Although the cuspal displacement was not completely avoided, alternative methods of photocuring should be considered to minimize the clinical consequences of composites contraction stress.

Keywords: Etch-and-rinse adhesive, Bonding technique, Polymerization, Cuspal movement.

INTRODUCTION

Dental resin composites have found increasing use as substitutes for dental amalgam due to their superior esthetics accompanied with good physical and mechanical properties. Most clinical problems of posterior resin composite restorations can be related to the polymerization of the material. During the polymerization process, a volumetric contraction varying between 1.5 and 5% can be observed, which results in the development of internal stresses. Additionally, the shrinkage stress can be manifested as cuspal movement, enamel cracks, dentin postoperative sensitivity and/or marginal gap formation that may compromise synergism at the restoration—tooth interface. This may lead to bacterial microleakage and ultimately pulpal inflammation or necrosis and secondary caries.

Different approaches have been recommended in order to prevent the problems inherent to polymerization contraction. One of them is decrease the irradiance of the light source or by using different photoactivation protocols as ‘soft start’, ‘ramp’, ‘pulse activation’ or ‘two-step’. Soft-start technique involves the so-called step-curing, where a reduced intensity of curing light is used during the first part of the polymerization period. The pulse-delay light-curing approach is characterized by delayed photo-polymerization (3-5 mins) between the low and high irradiance processes in order to allow the resin composite to adapt along the walls of the preparation before reaching the maximum gelation phase.

Studies reported that modulated photoactivation regimes improve the quality of marginal integrity. However, some researchers did not find benefit from modulated photoactivation. Therefore, positive impacts of the modulated photoactivation protocols on the resin composite restorations have been in a standing debate. The aim of the study was to investigate the effects of different polymerization protocols on the cuspal movement in class II composite restorations.

MATERIALS AND METHODS

Sixty extracted human premolar teeth were used in this study. The teeth were stored in 0.1% thymol solution at 5°C. All the restorative procedures were made under simulated dentinal hydrostatic pressure, employing a previously described protocol. A 1.5 mm diameter glass ball was fixed to each cusp.
Cuspal Movement related to Different Polymerization Protocols

The type of adhesive system did not influence the cuspal movement for all the curing methods. Standard protocol (1) showed the highest values of cuspal movement and was statistically different from the pulse-delay (2) and soft-start light (3) curing modes.

**DISCUSSION**

In general, light-curing units with very high intensity are recommended, based on studies of curing depths and physical properties of the resin composites. However, one must also consider the possible negative effect of high intensity lights on contraction stress development. During the light-curing procedure, resin composite is transformed from a viscous-plastic state to a rigid-elastic state. At the beginning of the polymerization, contraction of the composite is compensated by its viscous flow. Then, the viscous flow is reduced, and stresses are transferred to the tooth structures and bonding interface. This happens when the composite reaches its gel point. To reduce the stress, the resin composite should have enough time to flow, and relieve contraction forces. In this respect, it is understood that a variety of modulated photoactivation regimes decrease the polymerization rate and, consequently, the contraction stress.

It is important to note that the transfer of stresses to the adhesive interface and tooth structure occurs only in the presence of adequate bond between resin/tooth. In this sense, and knowing the performance differences between adhesives, three and two-step etch-and-rinse adhesives were used. Adhesives usually present different monomers and organic solvents and the latter can affect the mechanical properties as modulus of elasticity. It has been observed that the use of adhesives with low modulus of elasticity allow to act as a ‘stress breaker’. However, in this study, there was no difference between the two adhesive systems employed. So, it is not possible to extrapolate for all adhesive systems.

It has been demonstrated the reduction of polymerization contraction stress for dental composites by two-step light activation and that the use of a light with a higher power density may cause more rapid development of polymerization contraction. On the other hand, the use of lights with lower intensity may produce reduced rates of polymerization and allow more time for molecular rearrangements, decreasing the polymerization contraction stress. A previous study reported that the use of a low initial light intensity (270 mW/cm²) for 10 seconds followed by high intensity lights showed the highest values of cuspal movement and was statistically different from the pulse-delay and soft-start light.

**RESULTS**

The results of cuspal movement are presented in Table 1. The type of adhesive system did not influence the cuspal movement for all the curing methods. Standard protocol (1) showed the highest values of cuspal movement and was statistically different from the pulse-delay (2) and soft-start light (3) curing modes.

| Table 1: Means of cuspal displacement (µm) and standard deviation (SD) for the etch-and-rinse adhesives |
|-----------------|-----------------|-----------------|-----------------|
|                 | Standard        | Pulse-delay     | Soft-start      |
| SMP             | 16.1 (±6.2)     | 9.6 (±4.6)      | 8.5 (±3.5)      |
| SB              | 17.4 (±3.7)     | 7.3 (±3.9)      | 10.6 (±5.5)     |

Within each line, different lower case letters mean statistically difference; within each column, capital letters mean statistically difference (p < 0.05), SMP: Scotchbond Multi-Purpose; SB: SingleBond

light (600 mW/cm²) for 50 seconds provides the best adaptation of resin composite to cavity walls and possibly the least polymerization contraction stress. Additionally, another study observed that the two-step photoactivation protocol was preferable, since it resulted in a significantly lower cuspal deflection (11% lower, compared to the continuous illumination). The findings of the present study are in agreement with studies aforementioned showing that application of light intensity of less than the maximum resulted in a reduction of cuspal movement.

It is interesting to note that there was no difference between pulse-delay and soft starting curing. So, the use of soft-starting curing seems to be more appropriate for special patients, children and old-aged for not requiring a resting period. Additionally, enamel cracks and marginal gap formation were not evaluated, meaning that the lower values of cuspal movement does not necessarily mean best results in terms of clinical behavior.

On the other hand, two-step curing of resin composites may result in polymers with increased susceptibility to the action of softening substances in food and beverage. It has been demonstrated that the predominant reason for the reduced shrinkage stress attained with soft-start or pulse curing had a modest decrease in final conversion. Nowadays, the use of high intensity lamps (≥1200 mW/cm²) can eliminate this problem.

**CONCLUSION**

This study revealed that the cuspal displacement was not completely avoided, when pulse-delay and soft-start protocols were employed. Further researches are required in which alternative methods of photocuring should be considered to minimize the clinical consequences of composites contraction stress.
