A Dependable Device to Secure Condylar Position into Glenoid Fossa during Orthognathic Surgery

Pratik Dipak Shah, Srijon Mukherji

ABSTRACT

A change in condylar positioning is one of the areas of concern following orthognathic surgery which may occur due to numerous reasons like paralysis of the muscles of mastication, fixation methods, malalignment of the bone segments and more commonly due to inadvertent force used to bring the jaws in to occlusion. Deranged position of condyle may lead to relapse following surgery and also causes TMD sequelae. Condylar position in the glenoid fossa can be secured during orthognathic surgery by using condylar positioning device. The role and design of the condylar positioning device has been discussed in detail in this technical note.

Keywords: Orthognathic surgery, Condylar positioning device, Inadvertent force.

INTRODUCTION

A change in the position of the condyle may occur during orthognathic surgery for number of reasons. The recumbent position of the patient, paralysis of muscles of mastication, joint edema, malalignment of the bone fragments, methods of positioning the condyle, fixation methods and most commonly inadvertent force used to bring the jaws in to occlusion. The condylar positioning device has ability to reproduce condylar position in all three planes. It is a rigid device between the proximal segment of the mandible and a stable structure as maxillary dentition/splint or zygomaticomaxillary buttress. One would say it is obvious that condylar positioning devices to be used in orthognathic surgery. However, most surgeon do not prefer to use them routinely because, they are not easy to use and they require additional time. The first of such devices was developed by Luhr who adapted a bone plate between ramus and interocclusal splint. The purpose of this article is to discuss the role and unique design of condylar positioning device which we routinely use in our orthognathic surgery practise.

MATERIALS AND METHODS

Preoperatively we mold 2 mm width 10 hole titanium plate and secure over the skull and mandible (Fig. 1). Two bands are usually given. One at zygomaticomaxillary buttress region and the other at the proximal segment of the ramus of the mandible (Fig. 2). One Helicopter band is usually incorporated either at buttress or proximal region and proximal ramus segment of the mandible
ramal segment region (Fig. 3). Same design is transferred over the patient while performing orthognathic surgery. Before beginning with the osteotomy, patient’s jaws are brought in to a centric occlusion using acrylic wayer which is prepared preoperatively. After bringing the jaws in to centric relation maxillomandibular fixation is performed using tie wires. Once occlusion is achieved in centric relation, it is made sure that condyles are in the glenoid fossa. Then molded titanium plate is secured over the zygomaticomaxillary buttress region and proximal ramal segment of the mandible with minor modifications for precise adaptation. After that bone plate is removed and osteotomy is performed. Once distal segments of the jaws are brought into desired position after placing prefabricated acrylic splint, maxillomandibular fixation is performed. Again the same molded plate is secured to previously drilled holes before fixing the distal and proximal segments with miniplates and it is made sure that condyles are within the glenoid fossa.

A 19-year-old female patient reported to Calcutta Institute of Maxillofacial Surgery during the year June 2014 with complain of flattening of face. Patient had already undergone presurgical orthodontics. After cephalometric analysis, model analysis and clinical examination, treatment plan was established to perform high level Le Fort I advancement osteotomy. Bone plate was molded over the skull preoperatively and same design was transferred over the patient during surgery. Bone plate was secured before beginning of osteotomy and then removed. After Le Fort 1 advancement again bone plate was secured to previously drilled holes (Fig. 4).

RESULTS

Postoperatively, there were no significant changes in the occlusion which clearly indicates condyles were within the glenoid fossa.

DISCUSSION

Studies have shown, with autorotation of the mandible after superior maxillary repositioning, the mandibular condyles were positioned more posteriorly in to glenoid fossa. Tuinzing and Swart, studying dry mandibles showed that intercondylar distance decreased with bilateral sagittal ramus osteotomy to move the mandible backwards and increased when the mandible was advanced also using dry specimens, showed that condylar displacement tends to occur more frequently with screw fixation than with wire osteosynthesis after sagittal ramus osteotomy. In 1972 Mcmillen concluded that the muscles, especially the mandibular elevators are important in seating the condyles into their fossae. With paralysis of these muscles, the mandibular elevators are important in seating the condyles into their fossae.

With paralysis of these muscles, the mandibular elevators are important in seating the condyles into their fossae.
positioning device in Le Fort 1 osteotomy, it is made sure that it is fixed above the osteotomy line.

A change in condylar position less than 1 mm seems very good irrespective of the method used to achieve it. In the present case, there was no change in the occlusion from the desired position which clearly indicates condylar position change was less than 1 mm which is not significant.

CONCLUSION

Even though, condylar positioning device is difficult to use, too time consuming and considering the fact some adaptability of condyle that takes care of any malpositioning in most of the patients, It is still recommended to use for precise repositioning, harmonious, long lasting and stable results and to prevent TMD sequelae. Preoperatively molded titanium plate is comparatively easy to use as its adaptation to facial skeleton on patient becomes easy and saves additional time required for bending and adaptation.
