A Rare Case of Rhinofacial Zygomycosis due to Conidiobolus Infection

Arunabha Chakravarti, Meenakshi Mishra

ABSTRACT

Background: Rhinofacial zygomycosis is the infection of subcutaneous tissues of maxillofacial region caused by zygomycetes class of fungi. It is commonly caused by the order mucorales and is acute and fulminant. Infections by the order entomophthorales are rare but indolent.

Case report: We report an unusual case of rhinofacial zygomycosis due to Conidiobolus coronatus of the order Entomophthorales in an immunocompetent adult male to highlight the clinical presentation, diagnosis and treatment. We treated the patient with multiple drugs, that is amphotericin-B, cotrimoxazole, and itraconazole along with endoscopic debridement of nasal polyps with excellent result.

Conclusion: Rhinofacial zygomycosis due to entomophthorales is rare but treatable condition. Appropriate histopathological diagnosis and a multipronged approach with timely medical as well as surgical management is the key to clinical cure.

Keywords: Rhinofacial zygomycosis, Conidiobolus coronatus, Entomophthorales, Mucorales.

INTRODUCTION

Zygomycetes class of fungi is divided into two orders—entomophthorales and mucorales.1-3 Infections caused by entomophthorales are rare, and are known to be indolent, chronic, associated with granulomatous inflammation and a protracted clinical course. Entomophthorales comprises of two species, namely conidiobolus and basidiobolus. Conidiobolus species generally causes rhinofacial zygomycosis which is a chronic granulomatous infection of nose and face. We present here a case of rhinofacial zygomycosis in a healthy adult male caused by conidiobolus coronatus.
orally every 12 hours. Renal function tests were monitored closely. Endoscopic debridement of the nasal mass was performed and sent for fungal staining and histopathological examination which revealed granulomatous inflammation with fungal hyphae surrounded by eosinophilic precipitate. The report was consistent with *Conidiobolus* zygomycosis.

Injection amphotericin was given for 3 weeks till cumulative dose of 1 gm was reached after which the patient developed increased blood urea (60 mg/dl) and serum creatinine (5 mg/dl). Patient was then put on oral itraconazole 200 mg twice daily for duration of 4 months. Patient has been on regular follow-up since then and has shown no recurrence till date.

**REVIEW OF LITERATURE AND DISCUSSION**

Zygomycosis is the infection caused by large, occasionally septate fungi belonging to the class *Zygomycetes*, which is broadly divided into entomophthorales and mucorales. Entomophthorales infect immunocompetent patients and cause chronic, indolent type of disease. Mucorales cause mucormycosis, also known as rhinocerebral mucormycosis which is a fulminating fungal infection seen in immunocompromised patients and is a well-known clinical entity.

*Basidiobolus* infection typically involves the leg, thigh, and buttocks. Infection caused by *conidiobolus* affects the upper respiratory tract, with involvement of nasal and paranasal mucosa and extension to the skin of the nose, superior lip and frontoglabellar region. The first human case was reported by Lie kyan Joe in Indonesia in 1960. Since then, few isolated case reports of the disease have been reported from West Africa, Central Africa, America and Asian subcontinent.

*Conidiobolus* zygomycosis usually affects males in the age group of 20 to 50 years with outdoor activities. The mode of infection is not precisely known but, traumatic implantation or transmission by infected insect have been proposed. The disease begins in inferior turbinate and shows submucosal spread. It can extend through the natural ostia to the paranasal sinuses and to the subcutaneous tissues of the face (forehead, periorbital region and upper lip). Severe facial deformity and epistaxis are often the presenting symptoms. Our patient had severe nasal deformity, bilateral nasal obstruction, extensive nasal polyposis and epistaxis.

Histologically, entomophthorales are characterized by sparse, occasionally septate fungi surrounded by eosinophilic infiltrate referred to as ‘Splendore-Hoeppli phenomenon’. Frequently, the hyphae are phagocytosed within the giant cell. This is seen in the field of chronic inflammation.

Treatment of rhinofacial zygomycosis is both medical and surgical. Surgical debridement of affected paranasal sinuses followed by antifungal therapy is the treatment of choice. Various drugs are used for treatment as single agent or in combination therapy. Potassium iodide, cotrimoxazole, imidazoles, amphotericin-B have been used. Treatment should be continued for atleast 1 month after the patient is clinically cured. In our case, we tried multiple drug regime with amphotericin-B, cotrimoxazole, and itraconazole along with surgical debridement of nasal polyposis with excellent result. Otorhinolaryngologists should be aware of the existence of this entity in order to make a prompt and precise diagnosis so that early intervention can be done to reduce the morbidity.
